ABSTRACT: This paper introduces a scaling parameter to the Fletcher-Reeves (FR) nonlinear conjugate gradient method. The main aim is to improve its theoretical and numerical properties when applied with inexact line searches to unconstrained optimization problems. We show that the sufficient descent and global convergence properties of Al-Baali for the FR method with a fairly accurate line search are maintained. We also consider the possibility of extending this result to less accurate line search for appropriate values of the scaling parameter. The reported numerical results show that several values for the proposed scaling parameter improve the performance of the FR method significantly.

Keywords: Unconstrained optimization; Large-scale optimization; Line search framework; Nonlinear conjugate gradient methods; Fletcher-Reeves method.

طرق فليتشر-ريفس المحسنة استنادا إلى تقنيات موازنة جديدة

أمل السعيدي و محي الدين البعلي

المختصر: يقدم هذا البحث معامل موازنة لطريقة فليتشر-ريفس في طرق التدرج المترافقة غير الخطية. الهدف الرئيسي هو تحسين الصفات النظرية والعديدة لتلك الطريقة عند تطبيقها مع مستقيم بحث تقريبي على مسائل الأمثليات غير المقيدة. تبين إمكانية الحفاظ على صفات البحوث في الإعداد الكافي والتكافير الشامل لطريقة FR مع مستقيم بحث تقريبي بدقة معقولة. نأخذ في الاعتبار أيضًا إمكانية تعيم هذه القياسات إلى مستقيم بحث تقريبي باستخدام قيم متوازنة لمعامل موازنة. تظهر النتائج العددية وجود العديد من قيم معامل الموازنة لتحسين أداء طريقة FR بشكل ملحوظ.

الكلمات المفتاحية: الأمثليات غير المقيدة، مسائل ذات أبعاد عالية، مستقيم البحث ، طرق التدرج المترافقة غير الخطية، طريقة فليتشر-ريفس.

1. Introduction

This paper is concerned with the line-search Fletcher-Reeves (FR) conjugate gradient (CG) method for solving the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} f(x),$$

where \(f: \mathbb{R}^n \to \mathbb{R}\) is a smooth function and its gradient \(g(x) = \nabla f(x)\) is available for any value of \(x\). For a given starting point \(x_1\), the method defines a sequence of points \(\{x_k\}\) iteratively as follows. On each iteration, once the function value \(f_k = f(x_k)\) and the gradient value \(g_k = g(x_k)\) are calculated, a search direction \(d_k\) is defined such that the descent property \(d_k^T g_k < 0\) holds, assuming \(g_k \neq 0\) since \(g_k = 0\) holds at a solution of problem (1). Then it is possible to find a positive steplength \(\alpha_k\) and hence a new point.

† Some preliminary numerical results were presented at 5th International Conference on Numerical Analysis and Optimization (NAO-V), January 2020, Muscat, Oman
\[ x_{k+1} = x_k + \alpha_k d_k \]  

such that the function reduction \( f_k - f_{k+1} \) is sufficiently positive (see for example Fletcher [1]).

In the class of CG methods, the search direction \( d_k \) is defined initially by the steepest descent choice \( d_1 = -g_1 \) that satisfies the above descent property for \( k = 1 \). The other directions are defined by

\[ d_{k+1} = -g_{k+1} + \beta_k d_k, \]  

where \( \beta_k \) is the CG parameter. In particular, Fletcher and Reeves [2] propose the positive value of

\[ \beta_k = \frac{\| g_k \|^2}{\| g_k \|^2 \alpha_k^*} \]  

(referred to as \( \beta_k^{FR} \)), where \( \| \cdot \| \) denotes the Euclidean norm. If the exact line search equation

\[ d_k^T g_k = 0 \]  

is satisfied, which is guaranteed if the steplength \( \alpha_k = \alpha^* \) is obtained by solving the minimization subproblem \( \alpha^* = \arg\min_{\alpha} f(x_k + \alpha d_k) \) exactly, then the above descent property with \( k \) replaced by \( k + 1 \) is also satisfied. Since solving this subproblem exactly (referred to as exact line search) is impractical, inexact line search is usually used so that the descent property may not hold. In this case, choice (4) is replaced by \( \beta_k = 0 \) (i.e., direction (3) is reset to that of the steepest descent) so that the descent property holds for all \( k \) (for further detail, see for example Fletcher [1], Nocedal and Wright [3] and Pytlak [4]). Because this resetting may destroy the useful features of the CG method, in certain cases, many choices for replacing the CG parameter FR formula have been proposed (see for example Hager and Zhang [5] and the references therein). If exact line search is employed and \( f(x) \) is quadratic, all the directions generated via (3) are mutually conjugate. Hence, the gradients of \( f(x) \) at the different iterates are mutually orthogonal, i.e., we have

\[ g_{k+1}^T g_k = 0, \]  

and these formulae are reduced to the FR one (see e.g. [1, 3, 4]).

Our aim in this paper is to maintain the global convergence property of the FR method and improve its behavior by scaling formula (4) by \( \xi_k \) before using it in (3) (as in Al-Baali [6]). Therefore, the resulting scaled direction

\[ d_{k+1} = -g_{k+1} + \xi_k \beta_k d_k \]  

would be close to the steepest descent one if \( \xi_k \) is chosen sufficiently close to zero. Hence, by continuity, the corresponding class of scaled CG methods (referred to as ScFR when \( \beta_k = \beta_k^{FR} \)) would satisfy the descent and convergence properties that the steepest descent method has.

It is important to mention that Powell [7] and essentially Zoutendijk [8] show that the FR method with exact line searches converges globally, in the sense that \( \lim_{k \to \infty} \inf \| g_k \| = 0 \). This result has been extended by Al-Baali [9] to inexact line searches with a fairly accurate values of \( \alpha_k \), known as the first practical global convergence result for the FR method (see for example Nocedal [10]). Al-Baali has obtained this result based on showing that the sufficient descent condition

\[ d_k^T g_k \leq -c \| g_k \|^2 \]  

holds for some positive constant \( c \), assuming the steplength \( \alpha_k \) satisfies the strong Wolfe conditions

\[ f_{k+1} \leq f_k + \rho \alpha_k g_k^T d_k, \quad |g_{k+1}^T d_k| \leq \sigma \| g_k \|^2 \| d_k \|, \]  

for \( 0 < \rho < \sigma < \frac{1}{2} \). It is worth noting that a value of \( \alpha_k > 0 \) which satisfies these conditions, for \( 0 < \rho < \frac{1}{2} \) and \( \rho < \sigma < 1 \), can be found in a finite number of operations whenever the above descent property holds (see for example Al-Baali and Fletcher [11] and Fletcher [1]).

In Section 2, we show that the ScFR class of methods with \( \xi_k \in (0, 1] \) maintains the sufficient descent property that the FR method has for the strong Wolfe conditions (9) with \( \sigma < \frac{1}{2} \). We will also enforce this property for any line search technique with sufficiently small values of the scaling parameter \( \xi_k \). In addition, that section defines some choices for \( \xi_k \). In Section 3, we introduce the quasi-Newton feature to \( \xi_k \) for the FR method as considered by Al-Saidi et al. [12] for the scaled CG methods. Section 4 shows that the proposed class of ScFR methods maintains the global convergence property that the FR method has when the strong Wolfe conditions are employed with \( \sigma < \frac{1}{2} \). In Section 5, we study the behavior of the proposed ScFR methods by applying them to a set of standard test problems. It is shown that the proposed scaling technique improves the performance of the FR method significantly in many cases. Finally, Section 6 concludes the paper.

2. The ScFR Class of Methods

We now define the scaled FR (ScFR) class of methods as suggested by Al-Baali [6] for the CG class of methods. The author replaces the search direction (3) by (7), for \( k > 1 \), where \( 0 < \xi_k \leq 1 \) is the scaling parameter, and maintains \( d_1 = -g_1 \). Since the value of \( \xi_k = 0 \) reduces this direction to that of the steepest descent, it follows by
continuity that the ScFR class of methods, with values of $\xi_k$ sufficiently close to zero, has the sufficient descent and global convergence properties that the steepest descent method has.

We first define some values of $\xi_k$ that enforce the sufficient descent condition (8) as follows (Al-Baali [6]). We note that this condition holds for $k = 1$ and $c = 1$. We now prove this condition for $k \geq 1$ as follows. On substituting (7) into (8) with $k$ replaced by $k + 1$, we have

$$g_{k+1}^T d_{k+1} = -\|g_{k+1}\|^2 + \xi_k \beta_k d_k^T g_{k+1} \leq -c\|g_{k+1}\|^2,$$

(10)

Hence,

$$\xi_k \beta_k (d_k^T g_{k+1}) \leq (1 - c)\|g_{k+1}\|^2,$$

(11)

or equivalently by the FR formula (4),

$$\xi_k (d_k^T g_{k+1}) \leq (1 - c)\|g_k\|^2,$$

(12)

where $0 < c \leq 1$. This upper bound on $c$ is included because condition (11) cannot hold for $c > 1$ and $d_k^T g_{k+1} = 0$ (the exact line search option). We note that (11) holds if its left hand side is nonpositive or either $\xi_k$, $d_k^T g_{k+1}$ or $\beta_k$ is sufficiently close to zero.

This paper assumes that the CG parameter $\beta_k$ is given by the FR formula (4), unless otherwise stated, and defines $\xi_k$ such that (11) holds whether $d_k$ satisfies the sufficient descent condition (8) or not. For convenience, we start with the following result of Al-Saidi et al. [12] assuming $\beta_k$ satisfies (8).

**Theorem 1.** Consider the ScFR class of methods, defined by (2), (4) and (7) and assume that the search direction (7) with $\xi_k = 1$ satisfies the sufficient descent condition (8). Then, this condition remains satisfied for $0 \leq \xi_k \leq 1$.

**Proof.** When $k = 1$, $d_k = -g_k$ and hence condition (8) holds with $c = 1$. For $k \geq 1$, it follows from (7) that

$$g_{k+1}^T d_{k+1} = -\|g_{k+1}\|^2 + \xi_k \beta_k (d_k^T g_{k+1}).$$

(13)

If $\beta_k (d_k^T g_{k+1}) < 0$, it follows that

$$g_{k+1}^T d_{k+1} \leq -\|g_{k+1}\|^2,$$

which is (8) with $c = 1$ and $k$ replaced by $k + 1$, since $\xi_k \geq 0$. Otherwise, if $\beta_k (d_k^T g_{k+1}) \geq 0$, then (13) implies

$$g_{k+1}^T d_{k+1} \leq -\|g_{k+1}\|^2 + \beta_k (d_k^T g_{k+1}),$$

since $\xi_k \leq 1$. Hence, by the theorem assumption we obtain (8) with $k$ replaced by $k + 1$.

We note that this result remains valid for any value of $c > 0$ if the choice $\xi_k = 1$ is used when $\beta_k (d_k^T g_{k+1}) \leq 0$ as we consider below for some choices of $\xi_k$. It is important to note that if the strong Wolfe conditions (9) are employed with $\sigma < 1/2$, then the sufficient descent condition (8) holds for $c = c_\sigma = \frac{1 - 2\sigma}{1 - \sigma}$ (see Al-Baali [9], for detail). Thus, for any choice of $c \leq c_\sigma$, $\xi_k = 1$ and the ScFR method is reduced to the standard FR method. However, using values of $c > c_\sigma$ require defining $\xi_k < 1$, for which we suggest the following way.

If condition (11) holds with $\xi_k = 1$, then we use this value so that the CG search direction is unchanged. Otherwise, we choose $\xi_k$ such that condition (11) holds with equality. Thus, we choose

$$\xi_k = \left\{ \begin{array}{ll}
\frac{(1 - c)\|g_k\|^2}{\beta_k (d_k^T g_{k+1})} & \text{if } \beta_k (d_k^T g_{k+1}) > (1 - c)\|g_{k+1}\|^2, \\
1 & \text{otherwise},
\end{array} \right.$$

(14)

or equivalently for the ScFR method,

$$\xi_k = \left\{ \begin{array}{ll}
\frac{(1 - c)\|g_k\|^2}{d_k^T g_{k+1}} & \text{if } d_k^T g_{k+1} > (1 - c)\|g_k\|^2, \\
1 & \text{otherwise},
\end{array} \right.$$

(15)

In this case, it follows that

$$\xi_k \beta_k = \left\{ \begin{array}{ll}
\frac{(1 - c)\|g_{k+1}\|^2}{d_k^T g_{k+1}} & \text{if } d_k^T g_{k+1} > (1 - c)\|g_k\|^2, \\
\beta_k & \text{otherwise},
\end{array} \right.$$

(16)

which shows that scaling is employed only when $a_k$ is sufficiently remote away from the right hand side of a minimizer $a^*$. To be precise, $\xi_k = 1$ is used when $\beta_k (d_k^T g_{k+1}) \leq 0$, although in this case (11) holds for any value of $\xi_k > 0$. To obtain the least change in the CG parameter, $c$ should be chosen close to zero (in practice, the value of $c = 0.001$ seems reasonable as observed by Al-Saidi [13]). We also note that $\xi_k = 1$ usually is used for a fairly accurate line search ($\sigma \leq 0.1$). Thus, we consider the outline of the scaled FR (ScFR) method as in Algorithm 1 that is reduced to the standard FR method if $\xi_k = 1$ for all $k$. If in Step 2 exact line searches (or nearly so) are employed for all $k$, then Algorithm 1 is reduced to the standard FR method. In practice, we observed that the above scaling technique improves the performance of the FR method significantly in several cases (see Section 5, for details).

It is important to realize that the choice of $\xi_k^1$ in (15) is independent of the line search technique. However, if the strong Wolfe conditions (9) are employed, the first case of (15) could be replaced by a smaller value to obtain

$$\xi_k^2 = \begin{cases} \frac{(1-c)\|g_k\|^2}{\sigma|d_k^T g_k|} & \text{if } d_k^T g_{k+1} > (1-c)\|g_k\|^2, \\ 1 & \text{otherwise}. \end{cases}$$  

(17)

This choice satisfies the sufficient descent condition (11) with $\xi_k = \xi_k^2$, because $\xi_k^2 \leq \xi_k^1$ and we have $d_k^T g_{k+1} > 0$ and $\xi_k^2(d_k^T g_{k+1}) \leq \xi_k^1(d_k^T g_{k+1}) = (1-c)\|g_k\|^2$. Indeed, replacing $\xi_k^1$ by a smaller value, which we consider below, maintains the sufficient descent condition (12). In practice, for $c = 0.001$, we observed that choice (17) works better than (15).

We now consider the rearrangement of Al-Baali [6] for the FR parameter as

$$\beta_k = \eta_k^T g_{k+1}, \quad \eta_k = \frac{d_k}{\|d_k\|^2},$$

(18)

which is possible for most CG methods (e.g., see Hager and Zhang [5] and Narushima and Yabe [14] and the references therein). Using this form and observing that

$$d_k^T g_{k+1} \leq \|d_k\|\|g_{k+1}\|,$$

(19)

the first case of (15) can be reduced to obtain

$$\xi_k^3 = \begin{cases} \frac{(1-c)\|g_k\|^2}{\|d_k\|\|g_{k+1}\|} & \text{if } d_k^T g_{k+1} > (1-c)\|g_k\|^2, \\ 1 & \text{otherwise}. \end{cases}$$

(20)

To increase the interval for the scaling parameter, we use (19) again in the condition of (20) so that we obtain the following choice of Al-Baali [6]:

$$\xi_k^4 = \begin{cases} \frac{(1-c)\|g_k\|^2}{\|d_k\|\|g_{k+1}\|} & \text{if } \|d_k\|\|g_{k+1}\| > (1-c)\|g_k\|^2, \\ 1 & \text{otherwise}. \end{cases}$$

(21)

We note that the interval for using $\xi_k^4$ in (21) is larger than or equal to that used by (20) so that sufficiently large values of $c$ might be used. Indeed, in practice, we observed that choice (17) is preferable to (21). Thus, we will not provide further details about (21).

### 3. A Quasi-Newton Feature

One feature for choices (20) and (21) is given by Al-Baali [6] who shows that the values of $\xi_k \leq \frac{(1-c)\|g_k\|^2}{\|d_k\|\|g_{k+1}\|}$, where $\eta$ for the FR formula is given in (18), enforce some positive eigenvalues of the ScFR matrix

$$H_{k+1} = I - \xi_k d_k \eta_k^T,$$

(22)

noting that direction (7) (similar to that of Perry [15]) can be rearranged as follows

$$d_k^T g_{k+1} = -H_{k+1} g_k.$$

(23)

Thus, we introduce another feature to the ScFR method like that of Al-Saïdi et al. [12] for the CG methods by modifying the scaling parameter $\xi_k$ such that ideally the quasi-Newton condition

$$H_{k+1} y_k = \delta_k,$$

(24)

Where

$$\delta_k = x_{k+1} - x_k, \quad y_k = g_{k+1} - g_k,$$

(25)

holds, assuming $H_{k+1}$ approximates the inverse of Hessian of $f(x)$ at $x_k$. Because, in general, we cannot fulfill condition (24), we let
\[ \xi_k = \arg \min_{\xi} \|H_{k+1} y_k - \delta_k\| = \arg \min_{\xi} \|y_k - \delta_k - \xi (\eta_k y_k) d_k\|. \]  

(26)

Solving this minimization problem (see for example Al-Saidi et al. [12]), it follows that

\[ \xi_k^q = \frac{(y_k - \delta_k)^T d_k}{\eta_k y_k d_k d_k^T}. \]  

(27)

On substituting \(\eta_k\) for the FR formula (18), (27) is reduced to

\[ \xi_k^q = \frac{(y_k - \delta_k)^T d_k d_k d_k^T}{y_k g_{k+1} d_k d_k^T}. \]  

(28)

To maintain the search direction differs from that of the steepest descent, the values of \(\xi_k\) should be bounded away from zero. Since, in addition, the first case of (15) enforces the sufficient descent condition (12) with equality, and that replacing \(\xi_k\) by a smaller value keeps inequality (12) holds, we may enforce \(\xi_k \in [\hat{c}, 1]\), where \(\hat{c}\) is a small positive number. Thus, we modify (15), which defines \(\xi_k^i\), to

\[ \xi_k^{q1} = \begin{cases} (1 - c) \|g_k\|^2 \frac{1}{d_k^T g_{k+1}} & \text{if } d_k^T g_{k+1} > (1 - c) \|g_k\|^2 \text{ and } \xi_k^q \notin [\hat{c}, 1], \\ \min \left(1, \frac{(1 - c) \|g_k\|^2}{d_k^T g_{k+1}}, \xi_k^q \right) & \text{otherwise.} \end{cases} \]  

(29)

and modify (17), which defines \(\xi_k^{q2}\), to

\[ \xi_k^{q2} = \begin{cases} (1 - c) \|g_k\|^2 \frac{1}{\sigma (d_k^T g_k)} & \text{if } d_k^T g_{k+1} > (1 - c) \|g_k\|^2 \text{ and } \xi_k^q \notin [\hat{c}, 1], \\ \min \left(1, \frac{(1 - c) \|g_k\|^2}{\sigma (d_k^T g_k)}, \xi_k^q \right) & \text{otherwise.} \end{cases} \]  

(30)

Since choices (29) and (30) can be rewritten as \(\xi_k^{q i} = \min (\max (\xi_k^i, \hat{c}), \xi_k^q)\), for \(i = 1, 2\) respectively, we observe that \(\xi_k^{q i} \leq \xi_k^i\). Similarly, we modify any \(\xi_k^{q i}\), for \(i = 1, 2, 3, 4\), to \(\xi_k = \min (\max (\xi_k^q, \hat{c}), \xi_k^i)\). In practice, we observed that these modified choices with \(\sigma = 0.1\) and \(\hat{c} = 0.001\) improves the performance of \(\xi_k^2\) (further possible choices and details can be seen in Al-Saidi [13]). Therefore, the above choices for \(\xi_k\) are chosen to enforce the sufficient descent condition as shown in the following result which is an extension to Theorem 1.

**Theorem 2.** Consider the ScFR class of methods, defined by (2), (4) and (7), and let \(\xi_k = \xi_k^i\) or \(\xi_k = \xi_k^{q i}\), for \(i = 1, 2, 3, 4\). Then, the sufficient descent condition (8) holds for all \(k \geq 1\).

*Proof.* It is obvious for \(k = 1\). For \(k \geq 1\), \(\xi_k = \xi_k^i\). 1 \(\leq i \leq 4\), are chosen such that inequality (12) holds which is equivalent to the sufficient descent condition (10). Since \(\xi_k^{q i} \leq \xi_k^i\), 1 \(\leq i \leq 4\), inequalities (11) and (12) remain satisfied so that condition (10) holds. Hence, condition (10) implies (8). 

Introducing other features to the scaling parameter \(\xi_k\) are also possible. In particular, we could introduce the useful conjugacy condition \(y_k^T d_{k+1} = 0\). This equation with (7) holds if \(\xi_k = \xi_k^c = \frac{y_k^T g_{k+1}}{\beta_k y_k^T d_k}\) which exists if the Wolfe condition holds. Similarly if we consider the modified conjugacy condition of Dai and Liao [16], \(y_k^T d_{k+1} = \min \{\beta_k y_k^T d_k, 1\}\), we obtain \(\xi_k = \frac{(y_k - t d_k)^T g_{k+1}}{\beta_k y_k^T d_k}\) which reduces direction (7), for any \(\beta_k\) to the class of Dai and Liao.

It is worth noting that Al-Baali [6] defines a bound on \(\xi_k\) to ensure that matrix (22) is positive definite, but we do not consider it here because it may increase the value of \(\xi_k\) so that the sufficient descent condition (11) may not hold.

### 4. Global Convergence Property

We now study the possibility of imposing the global convergence property

\[ \lim inf_{k \to \infty} \|g_k\| = 0 \]  

(31)

to the ScFR methods which we proposed in the previous sections such that the sufficient descent condition (8) holds for all \(k \geq 1\). Therefore, we first state the following standard assumptions on the objective function.

**Assumption 1.**

1. The level set \(L = \{x: f(x) \leq f(x_0)\}\) is bounded,
2. The objective function \(f\) is continuously differentiable in some neighborhood \(N\) of \(L\),
3. The gradient \(g(x)\) is Lipschitz continuous, that is there exists a positive constant \(L\) such that

\[ \|g(x) - g(\bar{x})\| \leq L \|x - \bar{x}\| \text{ for all } x, \bar{x} \in N. \]  

(32)
Supposing Assumption 1 holds, Powell [7] and Zoutendijk [8] prove the ideal result that the FR method, defined by (2), (3) and (4), satisfies the global convergence property (31) if exact line searches are used. This means that impractical choice of \( \sigma = 0 \) in (9) is considered. Al-Baali [9], however, considers the practical strong Wolfe conditions with \( \sigma < \frac{\kappa}{2} \) to show that the sufficient descent condition (8) holds and extends the above global convergence result to the practical FR method. This result has been extended by Touati-Ahmed and Storey [17] to the interval \( 0 \leq \beta_k \leq \beta_k^{FR} \), while Gilbert and Nocedal [18] have extended it to
\[
-\beta_k^{FR} \leq \beta_k \leq \beta_k^{FR}.
\]
(33)

Thus, we obtain the following convergence result for the ScFR methods.

**Theorem 3.** Suppose Assumption 1 holds and let the ScFR class of methods be defined by (2), (4), (7), and \( |\xi_k| \leq 1 \). If the strong Wolfe conditions (9) are employed with \( \sigma < \frac{\kappa}{2} \), then the ScFR methods converge globally in the sense that limit (31) holds.

**Proof.** The ScFR methods are defined in the previous sections like the FR method, except that the FR formula \( \beta_k^{FR} > 0 \), defined by (4), is replaced by \( \beta_k^{ScFR} = \xi_k \beta_k^{FR} \). Because \( |\xi_k| \leq 1 \), conditions (33) hold and hence the result follows from that of Gilbert and Nocedal [18].

\( \Box \)

### 5. Numerical Results

To show the efficiency of the proposed scaling technique for the Fletcher-Reeves method, we describe some numerical results. The results are obtained by applying the FR method with several scaled choices to a set of 46 different type of unconstrained optimization problems; their function names are given in Table 1. They belong to the CUTE [19] and Moré, Garbow and Hillstrom [20] collections of test problems. We also include the simple quadratic function of Al-Baali (see for example Al-Saidi [13]). For each type of problem, we let the dimension \( n \) varies as 2, 10, 100, 1000, 10000 so that the total number of test problems is 230. All the ScFR methods that we consider are defined by Algorithm 1 and differ only in Step 5 for defining the scaling parameter \( \xi_k \) unless otherwise stated. For the purposes of an accurate comparison, we use in Step 2 for all methods the Matlab line search program routine of Al-Baali (which essentially written in Fortran by Fletcher) which computes a value of the steplength \( a_k \) that satisfies the strong Wolfe conditions (9) as described in Al-Baali and Fletcher [11] and Fletcher [1]. The run was stopped as in Step 1 when neither \( \|g_k\| \leq 10^{-6} \) or the number of iterations reaches \( 10^3 \). We consider the following algorithms:

- FR: the standard FR method, defined by Algorithm 1 with \( \rho = 10^{-4} \) and \( \sigma = 0.1 \) in Step 2 and \( \xi_k = 1 \) in Step 5.

IMPROVED FLETCHER–REEVES METHODS

- **ScFR**: same as FR except that in Step 5, \( \xi_k = \xi_k^i \), for \( i = 1, 2, 3, 4 \), defined by (15), (17), (20), and (21), respectively.

- **ScFRq\(i\), \( i \leq 4 \)**: same as ScFR except that in Step 5, \( \xi_k = \xi_k^{qi} = \min(\max(\xi_k^q, \hat{c}), \xi_k^l) \) with \( \hat{c} = 0.001 \), where \( \xi_k^q \) is given by (28).

We observed that ScFR1, ScFR4 and ScFRq\(i\), for \( i = 1, 3, 4 \), are less efficient than the others. Therefore, we will not give further details about them. Although it is possible to study the behaviour of other methods that we considered here, we do not consider them in our comparisons because they were less efficient than the above algorithms.

For a useful comparison, we used the performance profiles tool of Dolan and Moré [21], which compares some solvers on the above set of problems in terms of the number of line searches, the number of function evaluations, the number of gradient evaluations and CPU time, required to solve the problems. In general the performance profile \( P_M(\tau), \tau \geq 0 \), is defined by the formula

\[
P_M(\tau) = \frac{\text{number of problems where } \log_2(\tau_{P,M}) \leq \tau}{\text{total number of problems}}
\]

where \( \tau_{P,M} \) is the performance ratio of the number of line searches (similarly for the other measures) required to solve problem \( p \) by a method \( M \) to the lowest number of line searches required to solve problem \( p \). The ratio \( \tau_{P,M} \) is set to \( \infty \) (or some large number) if the method \( M \) fails to solve problem \( p \). The value of \( P_M(\tau) \) at \( \tau = 0 \) gives the percentage of test problems for which the M method is the best. The value for \( \tau \) large enough is the percentage of test problems that M method can solve. The relative efficiency and reliability of each method can be directly seen from the performance profiles: the higher the particular curve, the better is the corresponding method.

The performance profiles for the FR, ScFR2, ScFR3 and ScFRq2 algorithms are given in Figures 1. We observe that all scaling techniques improve the performance of the FR method substantially. We also observe that ScFR2 is slightly better than ScFRq2 and both of them perform better than ScFR1. Thus, ScFR2 seems to be the best of the ScFR algorithms.

![Figure 1. Comparison among FR, ScFR2, ScFR3 and ScFRq2 for \( \sigma = 0.1 \).](image)
To give further idea about the behaviour of these methods for a large value of $\sigma$, we repeated the run for the previous four methods but with $\sigma = 0.9$ instead of $\sigma = 0.1$ in Step 2. The comparisons are given in Figures 2. Although these figures show that the FR method failed to solve about 40% of the test problems which is expected, the three ScFR methods solved almost all problems successfully. Thus, the ScFR methods are superior to the FR method.

To choose the best choice for $\sigma$, we repeated the run for the best ScFR2 method, using the values of $\sigma = 0.1, 0.4, 0.7, 0.9$ and 0.9999 (for the first value, the method is referred to as ScFR2). The comparisons are given in Figures 3. We observe that the performance of the ScFR method as improves as $\sigma$ decreases in terms of the number of line searches, function evaluations and gradient evaluations. However, the choice $\sigma = 0.1$ is significantly better than the others in terms of CPU time. Thus, $\sigma = 0.1$ is the best value for all the measurements. Another useful observation is that the scaled methods solved all problems for not only $\sigma < 1/2$ but also for $\sigma \geq 1/2$. Thus, the scaled technique improves not only the good behaviour of the FR method when $\sigma$ is sufficiently small but also solved problems that cannot be solved by the FR method.

We now compare the ScFR2 method with some useful CG methods such as the Polak-Ribière-Polyak [22, 23], Dai-Yuan [24] and Hager-Zhang [25] methods. These methods (referred to as PRP, DY and HZ) are defined by Algorithm 1 with $\xi_k = 1$ in Step 5 and $\beta_k$ in Step 4 is given respectively by the following formulae:

\begin{align*}
\beta_k^{PRP} &= \frac{\gamma_k^T \mathbf{g}_{k+1}}{\|\mathbf{g}_k\|^2}, \\
\beta_k^{DY} &= \frac{\|\mathbf{g}_{k+1}\|^2}{d_k^T \mathbf{y}_k}
\end{align*}

and

**Figure 2.** Comparison among FR, ScFR2, ScFR3 and ScFrq2 for $\sigma = 0.9$.  

\begin{align*}
\beta_k^{PRP} &= \gamma_k^T \mathbf{g}_{k+1} \\
\beta_k^{DY} &= \frac{\|\mathbf{g}_{k+1}\|^2}{d_k^T \mathbf{y}_k}
\end{align*}
IMPROVED FLETCHER–REEVES METHODS

\[
\beta_k^{\text{HZ}} = \left( \gamma_k - 2 \frac{\|y_k\|^2}{y_k^T d_k} \right)^T g_{k+1} \cdot \frac{1}{y_k^T d_k}
\]

(36)

Using \( \sigma = 0.1 \), the comparisons of the methods are given in Figures 4. We see that ScFR2 performs a little better than DY and a little worse than PRP and HZ. Thus, the ScFR2 method is efficient and there is a room for improving it. The above numerical results show indeed that all the ScFR methods perform well and the ScFR2 method is the best of them.

6. Conclusion

We show that introducing a simple scaling technique to the well-known Fletcher-Reeves method maintains its global convergence property, improves its performance significantly and solved problems that cannot be solved by the FR method. Since the ScFR methods work well when the strong Wolfe conditions are used with \( \sigma \geq 1/2 \), it is expected to extend their global convergence to \( \sigma < 1 \). It is also worth testing further possible choices for the FR scaled parameter (e.g., similar to that applied to the DY method by Esmaeili et al. [26]).

Conflict of interest

The authors declare no conflict of interest.

Acknowledgment

The authors would like to thank the editor and two anonymous referees for their critical and constructive comments.
