A 14-year-old student boy was referred to our thoracic surgery department at a university hospital in Rabat, Morocco (November 2019) for a growing swelling of the suprasternal notch observed five weeks prior to his admission to our department (Figure: 1A). The vaccination protocol was complete including bacillus Calmette-Guérin (BCG). Clinical examination showed a well-limited, fluctuating swelling, 10 cm in diameter, located in the suprasternal notch, without movement on swallowing, and without associated cervical or axillary nodes. Blood tests were normal, except for an elevated erythrocyte sedimentation rate (45 mm/h). An ultrasound of the neck revealed a collection of thick fluid independent of the thyroid gland. Neck and thorax Computed tomography (CT) scan shows a fluid collection with densification of anterior and superior cervicothoracic fat.

Anterior and superior cervicothoracic fat measuring approximately 125 × 71 × 52 mm (Figure 1 B). Fine-needle aspiration and cytology (FNAC) were performed with pus aspiration; With negative microbiologic evaluation and cultures, the patient underwent surgical debridement (Figure 1 C). Histopathologic examination (Figure 1D) showed the presence of a giganto-cellular granuloma with caseous necrosis; mycobacterium tuberculosis culture was negative and the diagnosis of tuberculosis was confirmed by rapid PCR assay.

The patient received anti-tubercular treatment: 2 months of Rifampicin (R)-Isoniasid (H) - Pyrazinamide (Z) and 4 months of Rifampicin - Isoniasid (2RHZ- 4RH) with a good clinical response.
Written consent of the patient has been obtained for publication.

**Comment**

Tuberculosis can involve and disseminate all organs; chest wall tuberculosis is a rare extrapulmonary localization and reaching 20-40% of all tuberculosis cases.

Chest wall tuberculosis is a rare extrapulmonary location and accounts for 1-5% of all musculoskeletal involvement. Isolated supra-sternal soft tissue tuberculous cold abscess is exceptional. Differential diagnosis includes thyroid swelling vascular malformations, thyroglossal duct cysts, dermoid cysts, or reactive and infectious lymphadenitis.

In the PubMed database Khalil, Vijay and Asayama reported respectively three, one and one case of suprasternal Notch2-4. It has been more described in immunocompetent individuals but immunosuppression should be researched in all cases. The clinical expression is dominated by swelling, sometimes there is sternal pain.

Chest CT is the best examination to demonstrate the presence of costal or sternal lysis, pleuropulmonary and mediastinal lesions. Confirmation of TB disease is obtained by bacteriological and/or pathological data.

The geneXpert study is a rapid and efficient technique for the diagnosis of tuberculosis compared to microscopy.

Therapeutic management combines anti-tubercular medical treatment (6 to 12 months) with fine needle aspiration (FNA) for diagnosis and small swelling but surgical debridement is mandatory to reduce the risk of recurrence in other cases.

The resolution is generally good with the combination of anti-bacillary treatment within 6 months and complete surgical debridement can be performed to minimize local complications.

**Authors’ Contribution**

MB performed the observation. MEH and MK composed the manuscript. EHK edited the final draft.

All authors approved the final version of the manuscript.
